#### Abstract

We present a spectroscopic atlas of Deneb (A2 Iae) obtained with the long camera of the 1.22-m telescope of the Dominion Astrophysical Observatory using Reticon and CCD detectors. For $\lambda \lambda 3826-5212$ the inverse dispersion is $2.4 \AA \mathrm{~mm}^{-1}$ with a resolution of $0.072 \AA$. At the continuum the mean signal-to-noise ratio is 1030 . The wavelengths in the laboratory frame, the equivalent widths, and the identifications of the various spectral features are given. This atlas should provide useful guidance for studies of other stars with similar spectral types. The stellar and synthetic spectra with their corresponding line identifications can be examined at http://www.brandonu.ca/physics/gulliver/atlases.html

Key words. atlases - stars: early type - stars: individual: Deneb - stars: supergiants

## 1. Introduction

Deneb ( $\alpha$ Cygni, 50 Cygni, HR 7924, HD 197345, BD $+44^{\circ} 3541$, GC 28846, SAO 49941, ADS 14172, FK4 777, GCRV 12971, HIC 102098) is a relatively sharp-lined and unreddened prototype of the early A-type supergiants which are among the most luminous stars in the Milky Way and other spiral galaxies. Its spectral type is given as A2 Ia by almost all modern classifiers beginning with Morgan \& Roman (1950) and Keenan \& Hynek (1950). It is appropriate to add an e to the spectral type as emission line cores are seen in at least $\mathrm{H} \alpha$. The literature concerning Deneb and similar supergiants is extensive and convoluted.

The material described here was analyzed by Albayrak (1999, 2000) for his Ph.D. Thesis. It is a set of very high quality spectra obtained with modern electronic detectors on a

[^0]spectrograph with a known amount of scattered light which has been removed. By making the spectrum widely available in FITS and html formats along with the line identifications, we hope this material will be useful for many other studies.

## 2. Observations and reductions

This atlas of Deneb's spectrum from $\lambda \lambda 3826-5212$ was compiled from 2nd order exposures obtained with a Reticon and the SITe-2 CCD detector (with respective wavelength coverages of 67 and $63 \AA$ ) and the long camera of the $1.22-\mathrm{m}$ telescope of the Dominion Astrophysical Observatory (DAO) with a resolution of $0.072 \AA$ (two pixels) and a mean signal-to-noise $(S / N)$ ratio of 1030. The central wavelengths between $\lambda 3860$ and $\lambda 5180$ used $55 \AA$ offsets. A central stop in the beam removed light in the same manner as does the secondary mirror of the telescope. The exposures were flat fielded with exposures of an incandescent lamp, which was viewed through a filter, placed in the coudé mirror train. For the observations described here, we used the IS96B image slicer.

For a continuation of this atlas, first order exposures extending further to the red using the IS96R image slicer are being obtained with a resolution of $0.144 \AA$. These will be posted on the URL given below and described in a future publication.

Reticon exposures were reduced to one-dimensional FITS files using the stellar and lamp exposures with the Program

RET72 (Hill \& Fisher 1986). For CCD exposures we also used bias exposures and the program CCDSPEC (Gulliver \& Hill 2003). Bias and flat images were summed to provide mean bias and mean flat exposures. The mean bias exposures were subtracted from the mean flat and the arc and stellar exposures. Then the arc and stellar exposures were divided by the mean flat image. Cosmic rays were completely removed from the individual stellar exposures. Point spread functions perpendicular to the dispersion direction were used in an optimally weighted extraction in which the weights were proportional to the recorded intensity squared. Arc exposures were extracted using the same cross-sectional profile as the stellar images.

The arc files were measured interactively using the relevant routine in REDUCE (Hill \& Fisher 1986), a spectrophotometric reduction and analysis program. An initial approximation to the dispersion characteristics of each DAO spectrograph were input and corrections, based on the agreement between the predicted and measured position of each line, were used to predict the position of each new line. When the corrections became sufficiently small, the remaining lines were measured automatically. Heliocentric radial velocity corrections were applied using the program VSUN (Hill \& Fisher 1986). Wavelengthcalibrated spectra were produced with REDUCE using the arc files. The wavelength scale accuracy is better than $0.005 \AA$. Where there were multiple spectra of the same region, we added them with program TSTACK (Hill \& Fisher 1986) to increase the $S / N$ ratio. Each spectrum was weighted appropriately by its intensity value.

The radial velocity of each spectrum was measured using the program VCROSS (Hill \& Fisher 1986) that crosscorrelated the stellar spectrum with a synthetic spectrum with the same atmospheric parameters as Albayrak (1999) ( $T_{\text {eff }}=$ $9000 \mathrm{~K}, \log g=1.45$, solar composition and a microturbulence of $8 \mathrm{~km} \mathrm{~s}^{-1}$ ), produced by the program SYNTHE (Kurucz \& Avrett 1981). To increase the resolution of the cross-correlation function the synthetic spectrum was broadened only by a rotational velocity of $10 \mathrm{~km} \mathrm{~s}^{-1}$. The cross-correlation function was fitted by a Gaussian, the centroid and FWHM of which were allowed to vary. A zero background slope of the Gaussian fit was an important restriction. The mean error of the radial velocities, as shown in Table 1 , is $0.3 \mathrm{~km} \mathrm{~s}^{-1}$.

Stellar intensity files were rectified with REDUCE so that the continuum was calculated from locally averaged points. The rectification was completed by interpolating between the averaged data by Hermite spline functions, which always pass through the averaged continua at the selected wavelengths. The scattered light along the spectrum was assumed to be $3.5 \%$ of the continuum (Gulliver et al. 1996). The final atlas and the published equivalent widths reflect this correction.

Rectification points were chosen by a novel technique that involves the selection of suitable intervals from the synthetic spectrum of Deneb. The parameters of this synthetic spectrum included those already mentioned as well as a macroturbulent velocity of $14 \mathrm{~km} \mathrm{~s}^{-1}$, a $v \sin i$ of $25 \mathrm{~km} \mathrm{~s}^{-1}$ and a digitally sampled instrumental profile with a $F W H M$ of $0.072 \AA$. These rectification points need not be actual continuum points. A trial choice of suitable rectification points is based upon any wavelength interval for which the synthetic spectrum is roughly

Table 1. Deneb spectrograms.

smooth and there is good agreement with the observed spectrum. Obviously, good stellar parameters are a necessity. In effect this is an iterative process in which trial points are modified or rejected if there is not good agreement between the synthetic and observed spectrum. The process is complicated by poorly known atomic data for some lines which produce discrepant line strengths and positions in the synthetic spectrum. For any suitable rectification point, an intensity level is established from the synthetic spectrum and the observed spectrum is normalized at that value.

This technique can be used for any star that has well defined stellar parameters. It is particularly useful for rectification across broad hydrogen wings, for late type stars in which true continuum may be entirely absent and, as in this case, the appending of sections of spectra to produce a single monolithic spectrum. To facilitate the seamless combination of the sections there were at least two common rectification points over each 7 to $9 \AA$ overlap.

## 3. Atlas

The final monolithic spectrum is displayed at the URL http://www.brandonu.ca/physics/gulliver/deneb. The JAVA tool provided will allow the display and comparison, in any combination, of the observed and synthetic spectra and their respective line identifications. Unrectified or rectified sections of the Deneb spectrum, or the complete rectified spectrum, are also available as FITS format files from one of the authors (AFG) and the CDS. Copies of the line identifications are also available.

For the purpose of illustrating the nature of the atlas, Figs. 1 and 2 show the single section, centered at $4245 \AA$, of the Deneb atlas, which includes 25 such sections. The majority of the line identifications for this section are reproduced in the figures. The Java tool mentioned above would give a more accurate impression of the quality of the Deneb atlas.

## 4. Line identifications

For each line we employed the program VLINE (Hill \& Fisher 1986) to measure the equivalent width, the central wavelength, the line depth, and the full width at half maximum of the fitted profile, which was taken to be a Gaussian for most metal lines except the weak lines $(\leq 20 \mathrm{~m} \AA)$ which were rotational profiles and some He I lines which were Lorentzian profiles. Such line profiles are satisfactory for most lines. But the extended wings of Deneb's strongest metal lines can require additional components.

Our initial rotational velocity estimate based on nonblended lines with rotational profiles near Mg II $\lambda 4481$ was $27 \mathrm{~km} \mathrm{~s}^{-1}$. Such lines with equivalent widths of 10 to $18 \mathrm{~m} \AA$ are sufficiently weak to be unaffected by atomic line broadening, macroturbulence, and microturbulence and are clearly on the linear part of the curve-of-growth. During the later analysis of the macroturbulence via spectral synthesis technique, $v \sin i$ was refined to $25 \mathrm{~km} \mathrm{~s}^{-1}$ (Albayrak 1999, 2000).

To begin the line identification process, we identified the cleanest lines in the spectrum which are minimally affected
by noise. For Deneb this means lines with equivalent widths between 15 and 300 mA . These can often be found by examining stellar line identification list of stars of similar temperature, previous studies of Deneb, or working with standard references, in particular A Multiplet Table of Astrophysical Interest also known as the Revised Multiplet Table (Moore 1945). As not all atomic wavelength studies have equally well-determined wavelengths, one tries to find those which are consistent with modern determinations for Fe I and Fe II.

Stellar lines were identified with the general references A Multiplet Table of Astrophysical Interest (Moore 1945) and Wavelengths and Transition Probabilities for Atoms and Atomic Ions, Part 1 (Reader \& Corliss 1980), and selected references from the bibliography of Adelman \& Snijders (1974) whose most recent update is Adelman (2001). We used line identifications by Adelman and his associates for other stars which they have analyzed using DAO spectrograms, in particular $\gamma$ Gem (Adelman \& Gulliver, in preparation), $\sigma$ Boo (Adelman et al. 1997), and 2 Lyn, $\omega \mathrm{UMa}$, and $\phi \mathrm{Aql}$ (Caliskan \& Adelman 1997). We also compared our results with previous line-identified studies of Deneb, especially that of Groth (1961).

To derive the radial velocities we compared the observed and laboratory wavelengths of clearly unblended lines. For each spectrum we derived the average radial velocity and its standard deviation. If the observed stellar wavelengths as transformed to the laboratory frame yield many head-on coincidences, i.e., these wavelengths coincide with wavelengths of atomic species known or likely to be present, then the radial velocities are considered to be good. Table 1 lists the spectrograms with the their exposure numbers, Heliocentric Julian Dates at the mid-points of their exposures, an estimate of the $S / N$ ratio, and the derived radial velocities and their associated errors. The co-additions are labeled Wdeneb+the central wavelength in $\AA$. The $S / N$ ratio of each section was estimated from the root-mean-square deviation for the continuum point intervals, usually smooth regions without lines close to the continuum, as part of the rectification process. The CCD exposures generally show more consistent $S / N$ ratios for their whole spectral region than do the Reticon spectra. The more general, overall $S / N$ ratio of 1030:1 was determined by fitting an appropriately-filtered Fourier Transform to the entire spectrum.

Table 2 (accessible in electronic form) presents the full line identifications for $\lambda \lambda 3826-5212$. The identifications are available elsewhere as noted previously. To identify as well as possible the lines in the spectrum of Deneb an established procedure was followed. After the elemental abundances of Deneb were determined, a synthetic spectrum was calculated using Program SYNTHE (Kurucz \& Avrett 1981) with the adopted model atmosphere, solar abundances, the atomic data of Kurucz \& Bell (1995), the instrumental profile of the long camera of the DAO coudé spectrograph, and the other parameters found for Deneb by Albayrak $(1999,2000)$. It was a good, but not perfect match. A list of lines which contributed significantly to the spectrum was made and used to help identify unidentified features. For those lines not in other sources which are likely to be contributors, we used K as the multiplet number. The far left column

Fig. 1. $4245 \AA$ section of the Deneb Atlas $(\lambda \lambda 4215-4245)$.
contains the letters $L$ and $R$ are a guide to the range of lines whose wings are at least somewhat blended together. For example in Fig. 1, the features corresponding to Fe I 4219.360 and V II 4220.058 have their respective longward and shortward wings blended together and in Table 2 in the left col$u m n \mathrm{~L}$ and R are indicated, respectively. The columns are the measured stellar wavelength in $\AA$, the equivalent width $\left(W_{\lambda}\right)$ in $m \AA$, the line depth as a fraction of the continuum height, the line width $(F W H M)$ in $\AA$, the laboratory wavelength in $\AA$, which is the stellar wavelength as corrected for the stellar radial velocity of each spectrum, and the identified atomic lines which cause the observed feature. The stellar and the laboratory wavelengths should be close, but blending and errors can produce discrepancies. Possible identifications are given in parentheses and brackets indicate that an identified line may be contributing to two measured stellar features.

The following discussion indicates which atomic species were found in the observed spectral region. Usually no discussion is given for those species whose lines were found be absent. The major sources of the laboratory data which
supplement A Multiplet Table of Astrophysical Interest (Moore 1945) are given after each atomic species.

1. H I: All of the Balmer lines are found.
2. He I: Most of the He I lines are found while the forbidden components are difficult to see if present. Some He I lines are blended with lines of other elements or are close to the cores of Balmer lines. Lines which are definitely present belong to multiplets $4,5,11,12,14,16,18,20,47,48,50,51,52,53$, and 55.
3. C I (Moore 1993): Lines with laboratory intensities of 5 and greater are identified. The strongest lines include $\lambda 4771.747$ (multiplet 6), $\lambda 5052.167$ (multiplet 8), $\lambda 4932.050$ (multiplet 13), and $\lambda 4371.368$ (multiplet 14) with the largest equivalent width being $4.6 \mathrm{~m} \AA$.
4. C II (Moore 1993): Lines of multiplets 4 and 6 are present. Only $\lambda 4267.258$ is not severely blended.
5. N I (Moore 1993): The strongest lines with intensities of 10 and greater are present, but most are blended. Lines with definitely clean identifications include: $\lambda 4223.128$ (multiplet 5), $\lambda 4137.640$ (multiplet 6), $\lambda 4914.937$ and $\lambda 4935.121$

Fig. 2. $4245 \AA$ section of the Deneb Atlas $(\lambda \lambda 4245-4275$.
(multiplet 9), $\lambda 4660.455$ (multiplet 9.02), and $\lambda 3830.433$ (multiplet 11).
6. N II (Moore 1993): Two of the strongest lines $\lambda 4630.543$ (multiplet 14, intensity 15 ) and $\lambda 3994.998$ (multiplet 12, intensity 15 ) are clearly present as is $\lambda 4241.784$ (multiplet 48 , intensity 10). A few other strong lines might be present in blends.
7. O I (Moore 1993): The lines of multiplet 3 near $\lambda 3947$ appear to be blended with a Fe I line, those of multiplet 5 near $\lambda 4368$ are definitely present, $\lambda 4968.7931$ is possibly blended with an Fe I line, those of multiplet 16 near $\lambda 4773$ are weakly present, and $\lambda 5018.7832$ (multiplet 13 , intensity 5 ) is a possible identification. Hence lines of this species are probably present.
8. Na I: Lines of multiplet 8 are possibly present in blends, but are not marked.
9. Mg I: Lines of multiplets 3,11 , and 15 are clearly present. Those in multiplets 14 and 16 are blended.
10. Mg II: Lines of multiplets 4, 5, 9, 10, 18, 19, 21, 27, and 28 are present while some other lines are probably blended.
11. Al I: The two lines of multiplet 1 are present.
12. Al II: $\lambda 4663.054$ (multiplet 2) is identified with a $48 \mathrm{~m} \AA$ line. A few other lines might be present in blends.
13. Si I (Moore 1967): $\lambda 3905.523$ (multiplet 3) is blended with a Cr II line.
14. Si II (Moore 1965): Lines of multiplets 1, 3, 3.01, 5, $7.05,7.06,7.07,7.15,7.16,7.17,7.18$, and 23 are present.
15. S II (Pettersson 1983): Lines with intensities of 21 and greater are found often in blends. Some intensity 18 and 20 lines are found.
16. Ca I : The resonance line $\lambda 4226.728$ (multiplet 2 ) is present. Some lines with intensities of 40 and greater are in blends.
17. Ca II: The H, the K, and the $\lambda 4799.973$ lines are present.
18. Sc II: Lines with intensity 10 and greater are definitely present. Some weaker lines may be present.
19. Ti I: The strongest line $\lambda 3998.635$ (multiplet 12) is probably present as well as some other nearly as intense lines in blends.
20. Ti II (Huldt et al. 1982): Most lines with intensities of 5 or greater in Huldt et al. are present as well as some weaker
ones. 14806.321 is present according to data from Kurucz \& Bell (1995).
21. V II (Iglesias et al. 1988): Almost all lines with intensities $\geq 50$ are present as well as some lines with intensities between 15 and 45 . The intensity scale may be wavelength dependent.
22. Cr I (Kiess 1953): Lines of intensities 250 and greater are present. Weaker lines with intensities of 100 are often found in blends. A few lines with intensities as small as 50 are seen on occasion.
23. Cr II (Kiess 1951): Almost all lines with intensities 4 and greater are found. Some intensity 2 lines are found. A few predicted lines from Dworetsky (1971) and Kurucz \& Bell (1995) may be present.
24. Mn I: Lines only from multiplet 1 are present.
25. Mn II (Iglesias \& Velasco 1964): All lines stronger than intensity 100 are present. Some lines as weak as intensity 50 are found.
26. Fe I: Most lines with numerical intensities given are found. The wavelengths were updated using Nave et al. (1994).
27. Fe II: Most lines in Moore (1945) including predicted lines are found as are some lines from Dworetsky (1971) and Guthrie (1985). Almost all the lines in Johansson (1978) with intensities of 4 and greater are found as are most lines with intensities of 2 and 3 . Shortward of $\lambda 4800$, some lines with intensities of 0 and 1 found. For $\lambda \lambda 4800-5212$ we used Johansson as the primary source.
28. Fe III (Glad 1956): $\lambda 4419.599$, multiplet 4, is the only line definitely found. Kurucz \& Bell (1995) indicates in addition 24382.511 .
29. Co II: We found two lines in the region studied. Lines of Co II were found by Buscombe (1951) and Groth (1961) outside our observed wavelength range and are probably correctly identified.
30. Ni I: We used the wavelengths from Litzen et al. (1993). But only a few of the strongest lines are present, often in blends.
31. Ni II: All lines observed in the laboratory were found.
32. Sr II: The two strong lines of multiplet 1 are present.
33. Y II (Nilsson et al. 1991): Most of the strong lines with intensities greater than 1050 are present.
33. Zr II: Most lines with intensities 15 and greater are found along with a few as weak as intensity 7.
34. Ba II: Both lines of multiplet 1 are found, but in blends.
35. Cd I: There are features close to the position of the two strongest lines of multiplet $2 \lambda 5085.824$ and $\lambda 4799.918$. But $\lambda 4799.918$ is blended with an Ca II line which has a greater residual intensity. If one ignores the blend and calculates $\log$ $\mathrm{Cd} / \mathrm{H}$, the result is an excess of 3.91 dex relative to the Sun. This strongly suggests a misidentification.
36. La II (Meggers et al. 1975): The strongest lines $\lambda 3949.10$ and $\lambda 4086.72$ are probably present.
37. Eu II (Meggers et al. 1975): $\lambda 3930.50, \lambda 4129.73$, and $\lambda 4205.05$ suggest Eu II is weakly present.

Previously published line lists of Deneb include most of the lines which have equivalent widths $W_{\lambda} \geq 10 \mathrm{~mA}$. Most differences involve the weakest lines as would be anticipated. The new species of Deneb definitely found by this study are C I, N II, Si I, Fe III, Ba II, and La II. There is no evidence for
the presence of lines of A I (Taffara 1966; Zverko 1971), Si III, Ce II, Gd II, Hf II (Zverko 1971), Pr II (Groth 1961; Taffara 1966; Zverko 1971) and Cl II (Taffara 1966; Zverko 1971).

Small errors in the equivalent widths can effect the derived abundances, especially if the lines lie on the flat part of the curve-of-growth. Thus a necessary test between different analyses is a comparison of the derived equivalent widths of this analysis with the major studies of Deneb in the literature. Least squares comparisons in $m \AA$ of these values and those of this study (denoted by DAO) respectively for 31, 186, 302, 261, 154, 95 and 147 equivalent width values of Samedov (1993), Zverko (1971), Taffara (1966), Groth (1961), Chadeau (1955), Huang \& Struve (1955), and Buscombe (1951) yield:
$W_{\lambda}(\mathrm{DAO})=1.022 \pm 0.052 \mathrm{~W}_{\lambda}($ Samedov $)-5.832 \pm 4.310$
$W_{\lambda}(\mathrm{DAO})=0.802 \pm 0.015 \mathrm{~W}_{\lambda}$ (Zverko) $+9.524 \pm 3.159$
$W_{\lambda}(\mathrm{DAO})=0.772 \pm 0.015 \mathrm{~W}_{\lambda}($ Taffara $)+6.733 \pm 3.101$
$W_{\lambda}(\mathrm{DAO})=0.899 \pm 0.010 \mathrm{~W}_{\lambda}($ Groth $)+0.741 \pm 1.757$
$W_{\lambda}(\mathrm{DAO})=0.678 \pm 0.012 \mathrm{~W}_{\lambda}($ Chadeau $)-0.160 \pm 2.923$
$W_{\lambda}(\mathrm{DAO})=1.024 \pm 0.033 \mathrm{~W}_{\lambda}$ (Huang \& Struve)
$-5.270 \pm 7.546$
$W_{\lambda}(\mathrm{DAO})=1.026 \pm 0.022 \mathrm{~W}_{\lambda}($ Buscombe $)-8.690 \pm 4.086$.
For good agreement, one would expect the coefficient of the $W_{\lambda}$ term to be close to unity while the constant term to be close to zero. The differences come from scattered light, errors in the calibration procedure especially with photographic plates and continuum placement problems. Having the linear term not unity might reflect how the line profiles were drawn or errors in the plate calibration. A non-zero constant term implies a difference in placing the continuum either higher or lower according to its sign.

Recently Aufdenberg et al. (2002) calculated a non-LTE, line-blanketed, spherical expanding model atmosphere for Deneb with the PHOENIX code (Hauschildt \& Baron 1999) using a solar composition. They found $T_{\text {eff }}=8400 \pm 100 \mathrm{~K}$. A natural extension of their work and this investigation is to study the data of this atlas by adding the ability to vary the abundances in PHOENIX. We anticipate that problems with both analyses should be reduced. Such a study also provides an excellent justification to extend this atlas toward longward wavelengths.

Acknowledgements. SJA and AFG thank Dr. James E. Hesser, Director of the Dominion Astrophysical Observatory for the observing time. This research was supported in part by grants from TÜBİTAK (the Scientific and Technical Research Council of Turkey), the Turkish Academy of Sciences in the framework of the Young Scientist Award Program BA/TÜBA-GEBİ/2001-2-2), the National Sciences and Engineering Research Council of Canada, and The Citadel Foundation. We also appreciate the useful comments of the referee Dr. J. Zverko.
